Some have claimed that the medial prefrontal cortex (mPFC) mediates decision making. Others suggest mPFC is selectively involved in the retrieval of remote long-term memory. Yet others suggests mPFC supports memory and consolidation on time scales ranging from seconds to days. How can all these roles be reconciled? We propose that the function of the mPFC is to learn associations between context, locations, events, and corresponding adaptive responses, particularly emotional responses. Thus, the ubiquitous involvement of mPFC in both memory and decision making may be due to the fact that almost all such tasks entail the ability to recall the best action or emotional response to specific events in a particular place and time. An interaction between multiple memory systems may explain the changing importance of mPFC to different types of memories over time. In particular, mPFC likely relies on the hippocampus to support rapid learning and memory consolidation.

Introduction

The empirical literature on the medial prefrontal cortex (mPFC) is dominated by studies of its role in decision making, including conflict monitoring (Botvinick et al., 2004), error detection (Holroyd et al., 2002), executive control (Posner et al., 2007; Ridderinkhof et al., 2004), reward-guided learning (Rushworth et al., 2011), and decision making about risk and reward (Bechara and Damasio, 2005). However, the mPFC also plays a key role in memory, as highlighted by its selective involvement in the retrieval of “remote” memories (i.e., items learned several weeks earlier) (Bontempi et al., 1999; Frankland et al., 2004; Takashima et al., 2006b). Other studies implicate mPFC in “recent” memory, learned 1–2 days earlier. For example, inactivation of mPFC impairs the recall of fear memory learned the previous day (Corcoran and Quirk, 2007). Hence, the mPFC plays a role in both recent and remote memory. Other studies have emphasized the role of mPFC in the *consolidation* of memories, in that interfering with mPFC immediately after learning disrupts subsequent recall in many tasks (e.g., Tronel and Sara, 2003). All of these studies implicate mPFC in what might be defined as “long-term” memory (i.e., memory spanning several hours or longer). There is also evidence that mPFC is important for “short-term” memory, spanning seconds to minutes. For example, rats with mPFC lesions have difficulty recalling place-reward associations over a 30 min delay (Seamans et al., 1995) or waiting for a response cue over a 30 s delay (Narayanan et al., 2006). In summary, there is evidence that the mPFC plays a critical role in remote, recent and short-term memories over a broad range of tasks.

Theories of medial prefrontal function have emphasized its role in adaptive decision making. Earl Miller and colleagues have suggested that the entire prefrontal cortex receives a broad range of sensory and limbic inputs which can activate contextually appropriate representations of goals or task rules (Miller, 2000; Miller and Cohen, 2001). Active maintenance of these goals provide a “top-down” bias signal which can influence

stimulus-response mappings in other areas of the brain. They also suggest that outcome feedback drives synaptic plasticity in prefrontal cortex, ensuring that the appropriate goal state is enabled in the appropriate context (Miller and Cohen, 2001). Other theories, focused more specifically on mPFC, have suggested it guides decisions by anticipating emotional outcomes and enacting them as bodily states (Bechara and Damasio, 2005; Fellows, 2007).

This review represents an attempt to explain the mnemonic functions of mPFC as an aspect of the mPFC's more general role in guiding adaptive behavior. Our proposal builds upon the aforementioned theories but seeks to extend them to accommodate the burgeoning evidence implicating mPFC in different types of memory. Based on anatomical and electrophysiological evidence, we propose that mPFC takes as inputs the current context and events and predicts the most adaptive response based on past experience. Hence, what differentiates mPFC from other areas of the cortex is not its mnemonic capabilities, which we believe are shared with other cortical areas, but rather its specific involvement in guiding adaptive behavior. We further suggest that rapidly acquired input-output mappings in mPFC are initially supported by the hippocampus but later become independent. This framework unifies the known representational capabilities of mPFC with its role in a broad range of memory studies.

The mPFC Predicts Adaptive Responses

One of the most consistent findings regarding mPFC is that it is strongly modulated by motivationally salient events, both positive and negative. As exemplified in Figure 1, a large number of studies in humans, monkeys, and rodents have shown activity in ventral mPFC and medial orbitofrontal cortex (OFC) tied to the subjective value of anticipated or actual outcomes (Rushworth et al., 2011). In rodent mPFC, usually about one-third of cells show firing rate changes tied to reward and reward expectancy (Burton et al., 2009; Gruber et al., 2010; Pratt and

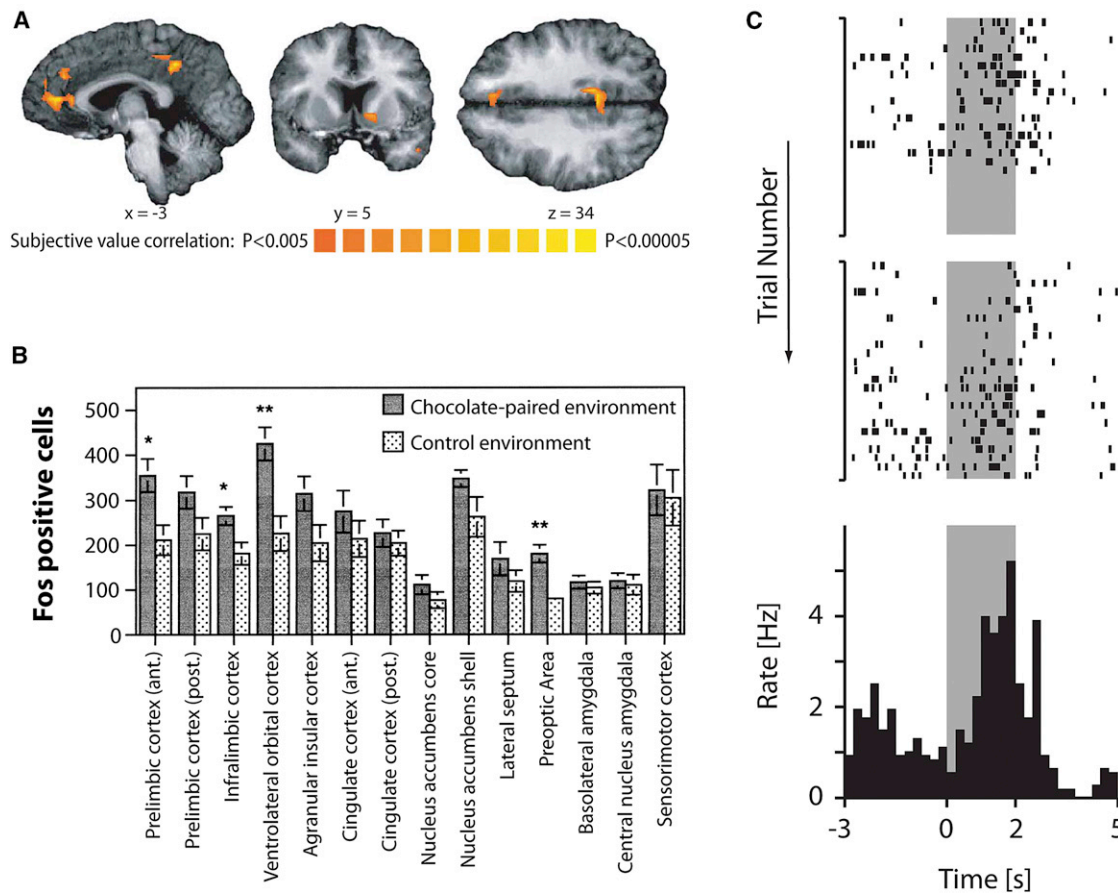

Figure 1. mPFC Encodes Expectation of Positive Outcomes

(A) Brain areas correlated with subjective value in humans. Subjects were asked to accept or reject offers of different amounts of money to be delivered after a specific delay. The mPFC, together with ventral striatum and posterior cingulate cortex, showed activity during the decision process related specifically to the subjective value of the current offer. The color scale represents the t value of the contrast testing for a significant effect of subjective value (Kable and Glimcher, 2007). Reprinted by permission from Macmillan Publishers, Ltd: *Nature Neuroscience*.

(B) Rat brain areas related to expectation of reward. Bars indicate relative numbers of Fos-positive cells in different brain areas after exposure to an environment where rats had previously been given chocolate chips compared to a neutral environment. Among cortical areas, there is selective activation of prelimbic and infralimbic cortex as well as lateral orbital cortex (reprinted by permission from Schroeder et al., 2001).

(C) Single-neuron encoding of reward expectation in rat mPFC. Rats had to enter a specific location and stay there until a food pellet was dropped at a separate location. Top two plots show spikes from one cell over two sessions. The bottom panel shows the binned perievent time histogram for both sessions. This cell shows ramping activity during the delay between zone entry at time 0 and pellet release at time 2 s (delay indicated in gray) (reprinted by permission from Burton et al., 2009).

Mizumori, 2001). Neural activity in mPFC is also strongly modulated by negative outcomes (Figure 2). Specifically, the primate rostral cingulate zone has been repeatedly found to be activated by the subjective experience of pain (reviewed in Shackman et al., 2011). The rodent anterior cingulate plays a similar role in the experience of pain (Johansen et al., 2001). Further, a subset of rodent mPFC cells respond selectively to the expectation of aversive events (Baeg et al., 2001; Gilmartin and McEchron, 2005). In primate anterior cingulate, partially overlapping groups of cells respond to both reward and lack of expected reward (Quilodran et al., 2008).

The involvement of mPFC, especially its ventral division, in motivationally salient events is also supported by anatomy. There appears to be a dorsal-ventral gradient in rodent mPFC, where ventral regions, including ventral prelimbic and infralimbic cortex, are specialized for autonomic/emotional control and dorsal regions, including anterior cingulate and dorsal prelimbic

cortex, are specialized for the control of actions (Gabbott et al., 2005; Heidbreder and Groenewegen, 2003). In fact, based on its connectivity, the ventral mPFC has been characterized as “visceral motor cortex” (Figure 3; Neafsey et al., 1993). Prominent among its connections are reciprocal projections to and from the amygdala and a unilateral projection to dorso- and ventromedial striatum. The ventral mPFC is strongly interconnected with anterior insular areas, known to be involved in both interoception (Allen et al., 1991) and pain perception (Jasmin et al., 2004). The ventral mPFC communicates with the hypothalamus, which mediates intrinsic homeostatic drives, such as hunger and thirst, and coordinates the autonomic and endocrine systems (Saper, 2003). Another prominent connection is with the periaqueductal gray, a region involved in aggression, defensive behavior, and modulation of pain (Nelson and Trainor, 2007; Sowards and Sowards, 2002). The ventral mPFC also provides the primary cortical input to the lateral habenula, an

(A) Pain-associated foci in human mPFC from a meta-analysis of 192 neuroimaging studies. Top panel: locations of individual activated foci associated with delivery of physically painful stimuli, such as heat, cold, or electric shock. Bottom panel: thresholded activation likelihood estimate (Shackman et al., 2011). Reprinted by permission from Macmillan Publishers, Ltd: *Nature Reviews Neuroscience*.

(B) Changes in blood flow in the rat brain during exposure to an environment previously associated with painful colorectal distention. Cerebral blood flow was imaged via radioactively labeled [^{14}C]iodoantipyrine. Colors indicate statistically significant differences between conditioned and control rats in positive (red) and negative (blue) directions (reprinted by permission from Wang et al., 2011). Abbreviations: fmi, forceps minor of the corpus callosum; HPC, hippocampus; PAG, periaqueductal gray; S1, S2, primary and secondary somatosensory cortex.

(C) Development of shock-anticipatory activity in mPFC during trace eye-blink conditioning. In box A, rats were exposed to a tone as a conditioned stimulus (CS) and, after a 500 ms delay, mild eye-shock as an unconditioned stimulus (US). In box B, CS and US were presented randomly so that the tone was not predictive of shock (pseudoconditioning). Within each of the two subplot on the left, each row shows a z score value for averaged population activity from all neurons showing an excitatory response during CS and trace interval. The horizontal axis indicates time within a trial and spans 1,800 ms. Early in training (rows below "Early"), mPFC cells respond primarily during the tone. After successful acquisition (rows above "Late"), cells maintain responses throughout the delay until delivery of shock. No such shock-anticipatory activity is evident in pseudoconditioned box B. The two panels on the right show similar results for all neurons showing an inhibitory response during the CS and trace interval (from Takehara-Nishiuchi and McNaughton, 2008. Reprinted with permission from AAAS.).

area involved in learned responses to pain, stress, anxiety, and reward (Hikosaka, 2010; Li et al., 2011). Finally, the ventral mPFC has bidirectional connections with a wide range of neuro-modulatory systems, including the dorsal raphe, ventral tegmental area, and locus coeruleus which, among other things, play an important role in adaptive responses to rewarding and stressful events (Itoi and Sugimoto, 2010; Kranz et al., 2010; Maier and Watkins, 2005; Schultz, 2001). The connections of the dorsal mPFC are similar to those of the ventral mPFC except that the dorsal mPFC has weaker connectivity with emotional and autonomic centers and stronger connectivity with motor and pre-motor areas (Gabbott et al., 2005; Heidbreder and Groenewegen, 2003; Hoover and Vertes, 2007). The dorsal mPFC in rats also projects directly to the spinal cord (Gabbott et al., 2005). In sum, the mPFC has access to information about motivational stimuli, including both pain and reward, as well as control over autonomic and skeletal-muscle activity.

Based on this evidence, we suggest that the inputs to mPFC are context and events and its output is the response which past experience predicts will lead to the most favorable outcome in a given situation (Figure 4). The term "context" often refers to any

set of cues which situate the animal in place and time, a type of information thought to be encoded by the hippocampus (Nadel, 2008). Here, we broaden the definition to additionally encompass the animal's emotional state (e.g., anger, fear). "Events" constitute both sensory cues and actions. In situations associated with aversive experiences, the most adaptive response may be a release of stress hormones and freezing. Conversely, appetitive situations might require approach toward a reward location. These outputs are trained by evaluative feedback signals which serve as inputs to mPFC. Just as visual cortex might map a pattern of visual inputs onto a particular object percept, the mPFC maps events onto the emotional or motoric response that will be most adaptive within a given context. Hence, what differentiates mPFC from other cortical areas is not its underlying functional architecture, but rather, its unique inputs and outputs. As with other cortical areas, memories in mPFC are probably schematic (i.e., they represent the gist or central tendency over a collection of experiences) rather than representing a single episodic event (McClelland et al., 1995; Winocur et al., 2010).

The inclusion of context and events as mPFC inputs is supported by electrophysiological evidence. Cells in mPFC are

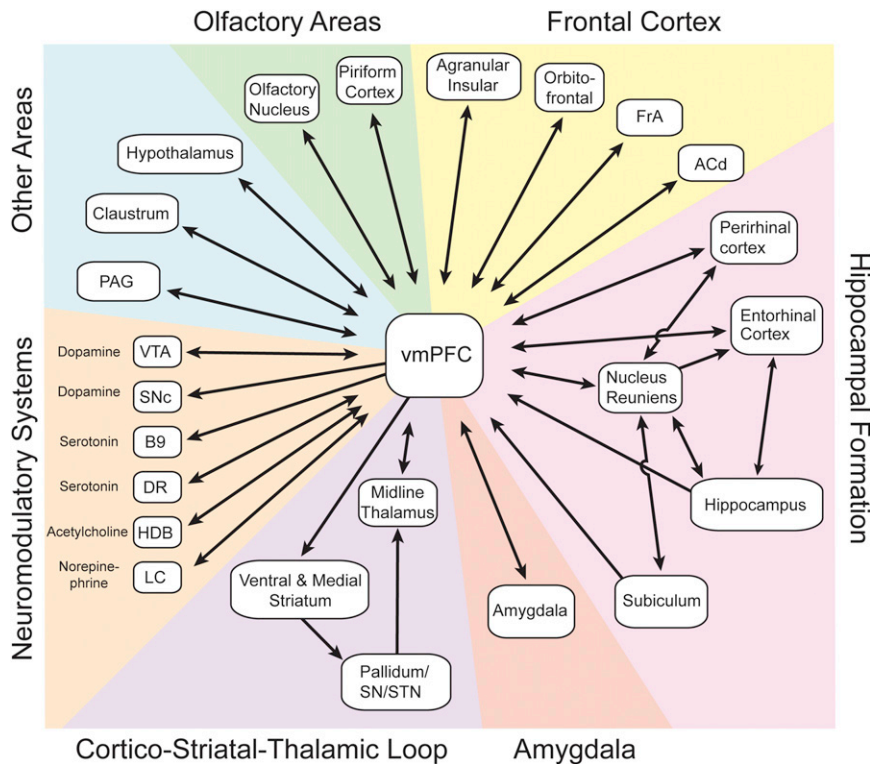

Figure 3. Major Anatomical Connections of Ventral mPFC

Arrows indicate directionality. Connections are derived from recent surveys of efferents and afferents of the mPFC and only the anatomically most dense projections are represented (Gabbott et al., 2005; Heidbreder and Groenewegen, 2003; Hoover and Vertes, 2007; Vertes et al., 2007). Hence, some potentially important connections, such as those to the lateral habenula, are not shown. Abbreviations: ACd, dorsal anterior cingulate cortex; B9, B9 serotonin cells; DR, dorsal raphe; FrA, frontal association cortex; HDB, horizontal limb of the diagonal band of Broca; LC, locus coeruleus; PAG, periaqueductal gray; SN, substantia nigra; STN, subthalamic nucleus, VTA, ventral tegmental area.

autonomic arousal in expectation of reward. However, the mPFC also exhibits robust responses to outcomes, both positive and negative. In fact, in both monkeys and rats, anticipated reward value and actual reward value have been shown to be encoded by separate groups of neurons (Amiez et al., 2006; Cowen et al., 2012; Pratt and Mizumori, 2001; Shidara and Richmond, 2002; Sul et al., 2010). A similar picture exists for negative

strongly modulated by which room an animal is in (Hyman et al., 2012). Further, location can modulate the responses to other events such as receipt of reward or lever pressing (Hyman et al., 2005, 2012; Miyazaki et al., 2004). Even subtle differences in position, as little as 1 cm, can change the firing of mPFC cells (Cowen and McNaughton, 2007; Euston and McNaughton, 2006). The temporal context of a task can also modulate mPFC firing; some cells respond selectively to specific task phases, such as the inter-trial interval (Jung et al., 1998; Lapish et al., 2008). Another aspect of context is task rules. Two studies have imposed a situation in which a rat is doing the same behavior (i.e., pressing the right lever) for different reasons (i.e., because it is visually cued or because all right presses are rewarded) and shown that the firing of some mPFC cells changes depending on *why* the animal is performing the action (Durstewitz et al., 2010; Rich and Shapiro, 2009).

Cells in mPFC also respond robustly to events, both motoric and sensory. The activity of single mPFC cells is often related to specific behaviors such as turning, running one direction on a path, and lever pressing (Cowen and McNaughton, 2007; Hyman et al., 2012; Jung et al., 1998; Narayanan and Laubach, 2006). When learning is involved, cells in mPFC can develop responses to cues or actions which predict reward (Mulder et al., 2000; Peters et al., 2005) or punishment (Gilmartin and McEchron, 2005; Laviolette et al., 2005; Takehara-Nishiuchi and McNaughton, 2008). The mPFC can also respond to salient cues, such as a tone, that are not tied to reward or punishment (e.g., Takehara-Nishiuchi and McNaughton, 2008).

In many cases, the response of mPFC to motivationally salient events may reflect the adaptive anticipatory response, such as

outcomes, though it is not clear that anticipated and actual outcomes are encoded by separate pools of neurons (Baeg et al., 2001; Gilmartin and McEchron, 2005; Takehara-Nishiuchi and McNaughton, 2008). In the framework presented here, the outcome-anticipatory signals are part of the mPFC *output* whereas outcome evaluative signals serve to drive learning and as such are part of the mPFC *input*. Outcome feedback signals, from areas such as ventral tegmental area, insular cortex, and hypothalamus, may drive synaptic changes via some form of reinforcement learning (Holroyd et al., 2002). Alternatively, it has been suggested that the mPFC compares actual and expected outcomes and computes the degree of expectancy violation (i.e., “surprise”) (Alexander and Brown, 2011). These surprise signals then drive learning within mPFC and elsewhere.

As previously mentioned, anatomical evidence suggests a dorsal-ventral gradient in which dorsal mPFC is action-related whereas ventral mPFC is more emotion-related. Consistent with this anatomical gradient, a recent rodent electrophysiology study showed that responses in dorsal mPFC were strongly driven by what the animal was doing (i.e., traveling down the left or right arm of a maze) while responses in ventral mPFC showed greater sensitivity to reward outcomes (Sul et al., 2010). The dorsal mPFC also supports sustained responses in motor cortex during a delay, demonstrating a direct functional link to motor systems (Narayanan and Laubach, 2006). The medial OFC has connectivity similar to the adjacent ventral mPFC while more lateral OFC receives sensory inputs, including visual, somatosensory, and olfactory (Hoover and Vertes, 2011; Reep et al., 1996). Because all frontal regions are interconnected, OFC may provide sensory inputs to mPFC (Hoover

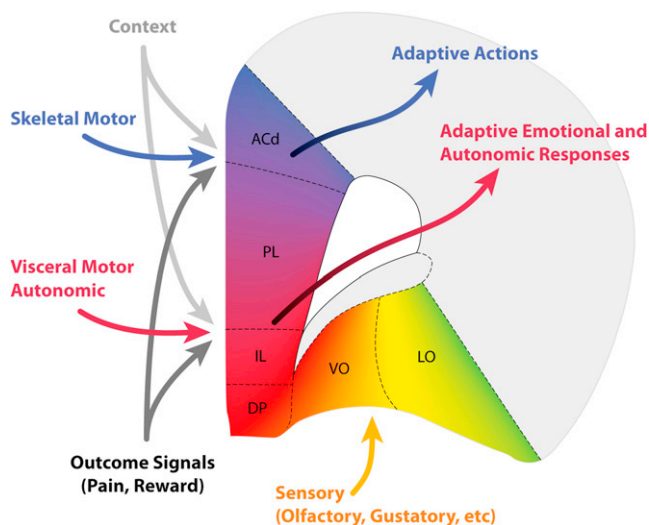

Figure 4. Schematic View of Hypothesized Inputs to and Outputs from Different Regions of Prefrontal Cortex

The mPFC is conceived as a network mapping events within a given spatial and emotional context with the most adaptive response, which can be either action or an emotional response, depending on the area. A separate set of inputs carries information about outcomes of actions, which modulate plasticity. All frontal areas are strongly interconnected, meaning that information about actions, emotions, and stimuli is available to all prefrontal areas. (figure based on Paxinos and Watson, 2007; altered with permission). Abbreviations: ACd, dorsal anterior cingulate; PL, prelimbic cortex; IL, infralimbic cortex; DP, dorsal peduncular cortex; VO, ventral orbital cortex; LO, lateral orbital cortex.

and Vertes, 2011; Jones et al., 2005). The evidence thus suggests the functional organization depicted in Figure 4. Dorsal mPFC receives information from motor regions and outputs adaptive actions. Ventral mPFC receives information from emotion-related structures and outputs adaptive emotional responses. Finer distinctions also exist. For example, the prelimbic and infralimbic cortex project to distinct regions of amygdala, with potentially important consequences for their role in fear learning and extinction (Peters et al., 2008).

The mPFC of primates follows a similar organizational scheme. Comparisons between rodents and primates are complicated by the debate over the homology of prefrontal regions (Brown and Bowman, 2002; Chudasama, 2011; Preuss, 1995; Seamans et al., 2008; Uylings et al., 2003). Based on functional evidence, some have claimed that mPFC in rodents represents an undifferentiated proto-PFC with functional aspects of both medial and lateral PFC in primates (Brown and Bowman, 2002; Uylings et al., 2003). The anatomical evidence, however, strongly suggests that mPFC in rodents is more similar to primate mPFC than lateral PFC (Preuss, 1995; Wise, 2008). Supporting this mapping, lesion studies in rats, monkeys, and humans suggest that dorsal anterior cingulate supports action-value associations while OFC supports stimulus-value associations (Camille et al., 2011; Ostlund and Balleine, 2007; Rushworth et al., 2011).

Role of mPFC in Long-Term Memory

Without other stipulations, the framework presented above predicts that the mPFC will be needed whenever context and

events guide behavior (i.e., during memory acquisition, as well as recent and remote recall). However, several studies suggest that mPFC plays a selective role in remote but not recent memory. We consider this evidence and discuss extant theories but conclude that mPFC is likely needed for both recent and remote memory.

Imaging studies were among the first to indicate a specific role for mPFC in long-term memory. An early study examined metabolic activity in 74 mouse brain regions during memory-guided retrieval of reward on an eight-arm maze either 5 or 25 days after learning (Bontempi et al., 1999). The mPFC, along with parts of frontal motor cortex and temporal cortex, showed significantly more activity during remote retrieval compared with recent. The selective activation of mPFC in remote memory has now been replicated using tests of both spatial and fear memory (Frankland et al., 2004; Maviel et al., 2004; Teixeira et al., 2006). Further, the density of dendritic spine growth in mPFC promoted by contextual fear conditioning is greater when measured at a remote time point as compared to a recent time point (Restivo et al., 2009). Imaging studies of socially transmitted food preference have also shown greater frontal cortex activity for remote memory, but in this task the effect is strongest in the OFC (Lesbarguères et al., 2011; Ross and Eichenbaum, 2006).

The aforementioned findings in rodents have parallels in the human imaging literature (see also Nieuwenhuis and Takashima, 2011). One study compared brain activation during recall of a recently learned stimuli (i.e., visual scenes) versus recall of a stimuli learned several weeks earlier. A small area in the subgenual anterior cingulate was the only brain region to show increasing activation with increasing memory retention intervals up to 90 days (Takashima et al., 2006a). Human imaging studies also suggest that mPFC plays a special role in memory consolidation during sleep. In one representative study, subjects studied word pairs and then were either deprived of the subsequent night of sleep or allowed to sleep normally. When tested for the words 6 months later, activity in the ventromedial PFC and occipital cortex was specifically elevated in subjects allowed to sleep when compared to subjects who were sleep deprived (Gais et al., 2007).

Consistent with these imaging results, inactivating mPFC leads to deficits in retrieval of remote memories while apparently leaving recent memory intact. This effect has been demonstrated across a range of tasks including the radial arm maze (Maviel et al., 2004), the Morris water maze (Teixeira et al., 2006), contextual fear conditioning (Frankland et al., 2004; Holahan and Routtenberg, 2007), and conditioned taste aversion (Ding et al., 2008). Corroborating evidence comes from drug addiction studies, which have shown that the mPFC is necessary for reinstatement of cocaine seeking at remote but not recent time points (Koya et al., 2009). While remote memory is usually examined roughly 30 days after learning, the selective involvement of mPFC in retrieval of remote trace fear memories has been shown at 200 days (Quinn et al., 2008). A final task showing a specific role for mPFC in remote memory is trace eye blink conditioning, in which an animal is conditioned to blink to a tone by pairing the tone, after a brief delay, with a mild eye shock. Lesions or inactivation of ventral mPFC in both rats and

rabbits selectively impair remote but not recent memories (Oswald et al., 2010; Takehara-Nishiuchi et al., 2006; Takehara et al., 2003).

Two theories have been forwarded to account for the specific involvement of mPFC in remote, but not recent, memory. It has been suggested that remote memories, being more difficult to recall, require stronger top-down cognitive control which is provided by the mPFC (Rudy et al., 2005). One issue with this approach is that top-down control over memory processes typically involves lateral prefrontal cortex rather than mPFC (e.g., Anderson et al., 2004). The other theory suggests that the mPFC takes over the role of the hippocampus in orchestrating the recall of remote memory (Frankland and Bontempi, 2005; Takashima et al., 2006b; Takehara-Nishiuchi and McNaughton, 2008). In other words, for recent memories, coherent patterns in hippocampus are sufficient to reinstate memories distributed across the neocortex. For remote memories, however, the mPFC supplies the necessary signals driving reinstatement. The necessary retrieval codes would presumably be transferred from hippocampus to mPFC during consolidation. In support of this model, it has been demonstrated that the hippocampus plays a role complementary to the mPFC, in that it is strongly activated during retrieval of recent memories but not remote memories (Frankland et al., 2004; Takashima et al., 2006b). Similarly, several studies have shown that the hippocampus is necessary for recent but not remote memory retrieval (Maviel et al., 2004; Takehara et al., 2003), although not all studies are consistent (Quinn et al., 2008; Teixeira et al., 2006). The primary weakness of this view, in our opinion, is that it does not naturally extend to other domains of mPFC function (e.g., decision making).

We propose that memories in mPFC consolidate like other cortical memories. During the initial encoding, mPFC starts to map between contexts, events, and adaptive responses, relying on hippocampus to support rapid learning. During consolidation, repeated replay of the memory results in a strengthening of synapses supporting the memory within mPFC. As mentioned previously, the mPFC (and the cortex in general) is likely extracting the regularities over a range of experiences rather than the details of a specific episode (McClelland et al., 1995; Winocur et al., 2010). The hippocampus has been hypothesized to encode memories via an arbitrarily assigned pattern of activity which does not itself contain the memory contents but rather is capable of reactivating the neocortical activity patterns that constitute the content of the memory (McClelland et al., 1995). Thus, during recent retrieval, mPFC represents the context, events and adaptive responses but not the mapping between them. After consolidation, mPFC stores both the inputs and outputs as well as the means to generate the former from the later. It follows that if the mPFC is needed for the retrieval of remote memory on a particular task, it should also be needed for the retrieval of recent memory.

Several lines of evidence support the involvement of mPFC in recent memory. First, at least two studies found that mPFC lesion or inactivation affected both recent and remote memory for fear conditioning (Blum et al., 2006; Quinn et al., 2008). Second, as discussed below, a large body of studies demonstrated that disruption of mPFC activity immediately after a task can impair performance on that task the following day.

In some cases, these latter studies focus on the same task and mPFC subregion as those used in remote memory studies suggesting no mPFC involvement in recent memory (e.g., compare Frankland et al., 2004; Zhao et al., 2005). Third, other studies have directly demonstrated the necessity of mPFC for the retrieval of recent navigational (Churchwell et al., 2010), object-place (Lee and Solivan, 2008) and fear memories (Corcoran and Quirk, 2007), learned 1 or 2 days before testing.

Despite strong evidence that mPFC is needed for both recent and remote memory, the many studies showing greater involvement of mPFC in remote memory cannot be ignored (see Table S1 available online). The most straightforward explanation is that mPFC participates in recent memory but plays an even greater role in retrieval of remote memory. Indeed, one study of contextual fear memory after mPFC lesion found a weak but significant impairment in recent memory and a stronger impairment in remote memory (Quinn et al., 2008). While our framework does not predict this phenomenon, it can be extended to accommodate the data. During the recall of recent memory, the role of mPFC is to represent context, events and responses while the mapping between them is stored within the hippocampus. During remote recall, on the other hand, the mPFC both *represents* and *stores* context-event-response mappings while the hippocampus becomes disengaged. Because mPFC serves for both storage and representation, the brain may be less able to compensate for its loss during remote retrieval than during recent.

Role of mPFC in Memory Consolidation

While the preceding section emphasized the role of mPFC in the *retrieval* of long-term memories, there is now considerable evidence that mPFC plays an important role in the *consolidation* of a wide range of memories. These studies demonstrate that activity in mPFC immediately *after* a task is needed for retrieval on subsequent days.

Evidence that mPFC is needed for stabilization of recently acquired memories spans a wide range of appetitive tasks. One study used an odor-reward association, acquired in just a few trials. When disruptive agents were injected into mPFC immediately after learning, subsequent testing 48 hr later revealed a severe memory impairment (Carballo-Márquez et al., 2007; Tronel et al., 2004; Tronel and Sara, 2003). Similar effects have been observed in lever-press for reward (Izaki et al., 2000), socially transmitted food preference (Carballo-Márquez et al., 2009), object recognition (Akirav and Maroun, 2006), and the Morris water maze (Leon et al., 2010).

Activity in mPFC immediately after learning is also important for the consolidation of fear memory. For example, interfering with mPFC plasticity immediately after trace fear conditioning (i.e., with a delay between tone and shock) has been shown to cause deficits in memory retrieval both 24 and 72 hr later (Runyan et al., 2004); however, the results for simple tone-shock fear conditioning are equivocal (Morrow et al., 1999; Zhao et al., 2005). Like trace fear conditioning, the consolidation of *contextual* fear conditioning is also dependent upon mPFC (Zhao et al., 2005). Contextual fear has also been examined using inhibitory avoidance. Interference with mPFC plasticity immediately after inhibitory avoidance training leads to deficits

at 24 and 48 hr (Holloway and McIntyre, 2011; Zhang et al., 2011). Interestingly, application of glucocorticoid receptor agonists to mPFC immediately after training actually enhances inhibitory avoidance (Roozendaal et al., 2009).

The ventral region of mPFC also plays a critical role in the consolidation of extinction of both fear and drug-related memories (Peters et al., 2009). Extinction is now known to be an active learning process involving the association between a conditioned stimulus and the absence of the unconditioned stimulus that was formerly associated with it. As with many other types of learning, disruption of synaptic plasticity in ventral mPFC after extinction training impairs memory for extinction of fear when tested 1–2 days later (Mamiya et al., 2009; Sotres-Bayon et al., 2009). Likewise, inhibiting mPFC after each daily extinction session leads to impaired extinction of drug craving (LaLumiere et al., 2010). Intriguingly, a recent study demonstrated *enhanced* fear extinction when the ventral mPFC was treated with a plasticity enhancing agent after extinction training (Marek et al., 2011).

There appears to be a critical window for consolidation in that chemical disruption of mPFC 1 to 2 hr after learning causes memory impairment whereas disruption outside this window does not (Carballo-Márquez et al., 2007; Izaki et al., 2000; LaLumiere et al., 2010; Takehara-Nishiuchi et al., 2005; Tronel and Sara, 2003; see Table S1 available online). What is the nature of mPFC activity during this critical posttask period? Consolidation theory suggests that during off-line periods, most notably sleep, the hippocampus reactivates recently learned experiences which, in turn, causes replay of these events in the neocortex. Replay allows new memories to become integrated with previous cortical memories and hence, more robust to interference (i.e., “consolidated”) (McClelland et al., 1995). In support of this theory, spike patterns corresponding to task activity have been shown to replay in hippocampus and several cortical areas during the rest period immediately following a task (Hoffman and McNaughton, 2002; Ji and Wilson, 2007; Wilson and McNaughton, 1994). Recently, robust replay has been observed in mPFC and an associated structure, the nucleus accumbens (Euston et al., 2007; Lansink et al., 2009). In both structures, replay occurs at an accelerated rate relative to that seen during behavior. Further, this replay is selective for recently learned events, suggesting a causal link in memory formation (Peyrache et al., 2009).

A critical issue is whether replay in mPFC is orchestrated by the hippocampus. Considerable evidence suggests that it is. Reactivation in hippocampus is tied to local field potential features called “sharp waves” (Kudrimoti et al., 1999). Likewise, reactivation in mPFC is strongest during periods with a high density of field potential oscillations known as “low-voltage spindles” (Johnson et al., 2010). These two hallmarks of memory reactivation, hippocampal sharp waves and cortical low-voltage spindles, tend to occur within a few hundred milliseconds of one another (Battaglia et al., 2004; Mölle et al., 2006; Siapas and Wilson, 1998; Sirota et al., 2003). Further strengthening the link, sharp waves in hippocampus have recently been shown to be correlated with memory replay in mPFC (Peyrache et al., 2009). The directionality of the mPFC-hippocampal interaction during sleep has been difficult to discern, with some results suggesting

events in hippocampus precede those in cortex (Battaglia et al., 2004; Wierzynski et al., 2009) while others suggest the opposite (Isomura et al., 2006; Mölle et al., 2006). Perhaps both sides are correct. It has been suggested that cortical events initiate hippocampal replay, which in turn reinforces the ongoing replay of patterns in the neocortex (Sirota et al., 2003). Alternatively, the directionality of information flow from hippocampus to mPFC may depend on whether the information being processed is newly learned.

One puzzling aspect of these consolidation findings is that tasks affected by posttask mPFC disruption are not necessarily mPFC-dependent during initial learning. For example, odor-reward associations tested 48 hr after learning are impaired by consolidation block, yet rats with prelimbic lesions can easily acquire and retrieve odor-reward associations within a single session (Birrell and Brown, 2000; Tronel and Sara, 2003). Likewise, a NMDA antagonist injected into infralimbic cortex *after* extinction training interferes with the consolidation of fear extinction but NMDA receptor block *during* extinction training has no effect on within-session acquisition of extinction or subsequent recall (Mamiya et al., 2009). Instrumental conditioning of lever pressing for food reward shows a similar pattern (Izaki et al., 2000; Ostlund and Balleine, 2005) as does object recognition (Akirav and Maroun, 2006; Ennaceur et al., 1997). The framework presented here predicts that mPFC will be involved in initial acquisition, consolidation, and retrieval of context-event-response associations. Hence, it cannot fit these data without additional stipulations. One possible explanation is that other prefrontal cortical areas can compensate for mPFC loss during learning but not during consolidation or recall. For example, aspects of odor-reward association may be mediated by both the OFC as well as ventral mPFC. If ventral mPFC is off-line during learning, OFC may become more heavily involved to the point that it can support learning independently. If mPFC is on-line during learning, however, the mPFC remains essential for consolidation and recall.

Role of mPFC in Short-Term Memory

Numerous research paradigms implicate mPFC in short-term memory, operationally defined here as memory spanning seconds to minutes. Historically, considerable emphasis has been placed on the role of mPFC in memory spanning intervals less than a minute, a capacity referred to as “working” memory (Uylings et al., 2003). Similar to primates with damage to dorsolateral prefrontal cortex, rats with mPFC damage often show deficits in tasks requiring a delayed response (e.g., Horst and Laubach, 2009). The functional similarity between rodent mPFC and primate dorsolateral prefrontal cortex is further bolstered by demonstrations that both exhibit persistent cellular activity during delay periods that is selective for a prior or upcoming target location (Baeg et al., 2003; Batuev et al., 1990; Funahashi, 2006). The idea that mPFC is specialized for working memory, however, has been undermined by recent findings. First, some of the most compelling evidence that mPFC plays a role in working memory are studies demonstrating that performance of rats with mPFC lesions gets worse with longer retention delays. However, in some of these studies, delay length is confounded with task novelty (Gisquet-Verrier and Delatour,

2006). In one example, mPFC-lesioned rats trained using a 5 s delay show impairment when switched to a 20 s delay (Delatour and Gisquet-Verrier, 1999); however, rats trained from the beginning on a randomly shuffled range of delays fail to show deficits (Gisquet-Verrier et al., 2000). Second, neurons in mPFC are highly selective to slight changes in position or trajectory (Cowen and McNaughton, 2007; Euston and McNaughton, 2006; Fujisawa et al., 2008). It is difficult to rule out the possibility that some, if not all, delay-related neural activity is entirely reflective of an “embodied memory” strategy involving differential behavior during the delay, rather than working memory per se. Indeed, it has been suggested that the primary deficit in rats with mPFC lesions is not information storage but rather the implementation of mediating strategies (Chudasama and Muir, 1997). Finally, working memory in some studies is confounded with memory for the rules of the task (i.e., reference memory). As an illustration, Touzani et al. (2007) trained mice on a spatial win-shift task in which the correct choice depended on which maze arm was rewarded two trials back. Consistent with the hypothesis that mPFC supports working memory, mice with mPFC lesions were incapable of acquiring this task. However, mice given mPFC injections of a protein synthesis blocker *after* each daily training session were also impaired. The lack of treatment during the task reduces the likelihood of interference with working memory. Instead, the impairment is likely due to disruption of consolidation which precluded acquisition of the task rules. In summary, many studies of working memory implicate the mPFC. Unfortunately, it is often difficult to determine whether the observed deficits are due to a breakdown in trial-specific working memory, mediating strategies, or a deficit in reference memory.

Despite these concerns, a few well-controlled studies do support a role for rodent dorsal mPFC in working memory for actions. One study showed impairments in delayed spatial alternation despite the researchers' careful efforts to rule out mediating strategies (Horst and Laubach, 2009). Another showed that when rats were required to hold down a lever until cued, one-third of dorsal mPFC cells were significantly modulated during the delay (Narayanan and Laubach, 2006). Further, half of these were predictive of errors (i.e., premature release). A follow-up study showed that one-fifth of dorsal mPFC neurons respond differently after error trials and maintain this activity into the next trial (Narayanan and Laubach, 2008). Hence, mPFC cells exhibit properties consistent with short-term maintenance of memory for action and errors.

There is also evidence that mPFC plays a role in memory spanning minutes to hours, but only in certain circumstances. In general, forming a short-term memory for locations, odors, or objects does not require the mPFC (Birrell and Brown, 2000; Ennaceur et al., 1997; Seamans et al., 1995). For example, rodents with mPFC inactivation show normal performance in free foraging in an eight-arm maze (Seamans et al., 1995). However, the task does become mPFC dependent if run as a spatial “win-shift” task (Seamans et al., 1995). In this variant, rats are initially rewarded on four arms and, after a delay of 30 min, are tested for their ability to locate the previously nonrewarded arms. Surprisingly, the role of mPFC is limited to the retrieval phase; inactivation of the mPFC before training or the delay has no effect on test

performance (Floresco et al., 1997; Seamans et al., 1995). Short-term memory for rewarded odors depends on mPFC when either a large number of odors must be remembered or odor associations must be acquired via social interaction (Boix-Trelis et al., 2007). In one example, rats with mPFC lesions were impaired when required to remember 10 sample odors over a 10 min delay (Farovik et al., 2008). In comparison, short-term memory for objects, tested via novel object preference, does not require the mPFC (Ennaceur et al., 1997). To our knowledge, no within-session object-recognition task has shown mPFC dependence.

Interactions with Hippocampus

Given the prominent role of the hippocampus in memory, it is no surprise that the hippocampus and mPFC are anatomically related. Compared to other cortical areas, projections from the ventral half of the hippocampus and subiculum to mPFC are particularly strong (Cenquizca and Swanson, 2007; Jay and Witter, 1991). The pathway is unidirectional but may be reciprocated via a bisynaptic route through the nucleus reunions or lateral entorhinal cortex (see Figure 3; Burwell and Amaral, 1998; Vertes et al., 2007).

The evidence supports two possible roles for the hippocampal input to mPFC: to provide context or to enable rapid associative learning. The ability of the hippocampus to encode spatial location via “place fields” is well known (Wilson and McNaughton, 1993). However, as one moves along the septal (dorsal)—temporal (ventral) axis, place fields become progressively larger (Jung et al., 1994). Ventral hippocampal fields are so large that they probably encode global context (i.e., which room the animal is in) (Kjelstrup et al., 2008). Accordingly, the mPFC, whose inputs arise mostly from ventral and intermediate hippocampus, exhibits no evidence of place cell-like responses but does discriminate between rooms (Hyman et al., 2012; Jung et al., 1998; Poucet, 1997). Recent evidence has established that the firing of hippocampal place cells is modulated by environmental stimuli (Leutgeb et al., 2005). Given its strong connectivity with limbic structures, ventral hippocampus may encode nonspatial contextual signals for such things as odors, bodily states, and emotions (Pennartz et al., 2011). Hence, as has been previously suggested, the hippocampal input is a plausible source of spatial and emotional context (Jung et al., 1998; Pennartz et al., 2011). The other possible role for hippocampal input to mPFC is to support rapid learning. Wise and Murray (2000) have provided evidence that arbitrary visual-motor mappings formed within premotor cortex initially depend on rapid associative mechanisms within the hippocampus but, through consolidation, become hippocampally independent. A similar principle may apply to the mPFC. To wit, the rapid formation and consolidation of associations between contexts, events, and responses within mPFC may depend on hippocampus, whereas long-term storage may be mediated mostly by mPFC. The aforementioned evidence for coordinated memory replay in the hippocampus during consolidation supports this claim.

The role of communication between hippocampus and mPFC has been studied via functional disconnection, in which the mPFC is inactivated in one hemisphere and the hippocampus is inactivated in the other. Because the connections between

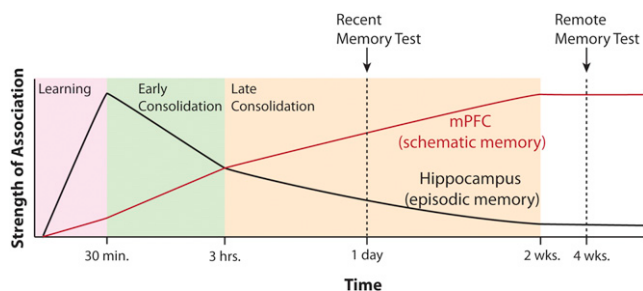

Figure 5. Proposed Timeline of mPFC's Role in Memory

Vertical axis is the strength of the memory stored in either mPFC or hippocampus while horizontal axis indicates time on a log scale. During 30 min of task learning, the hippocampus learns more quickly than mPFC. During early consolidation, the hippocampus supports memory replay and the development of schematic representations within mPFC. Concurrently, episodic memory traces within hippocampus decay. This process continues during late consolidation, albeit at a slower rate.

hippocampus and mPFC are unilateral, the animal is left with one intact hippocampus and one intact mPFC but no pathway between them (Floresco et al., 1997). This technique has been used to demonstrate that mPFC-hippocampal communication is necessary for short-term memory in paradigms including the water maze (Wang and Cai, 2008), the T maze (Wang and Cai, 2006), spatial win-shift on the radial arm maze (Floresco et al., 1997; Goto and Grace, 2008), and the Hebb-Williams maze, a spatial maze requiring a specific set of turns to reach reward (Churchwell et al., 2010). In fact, the effects of mPFC-hippocampal disconnection are nearly the same as those seen after bilateral mPFC inactivation, supporting the claim that mPFC is dependent upon the hippocampal-mPFC pathway either for context or for rapid learning.

As further evidence for a functional interaction between mPFC and hippocampus, electrophysiological rhythms in these two structures are coupled, particularly in the theta range. Roughly half of mPFC cells exhibit phase locking to hippocampal theta while rats engage in spatial tasks (Hyman et al., 2005; Siapas et al., 2005). More importantly, this synchronous activity is associated with memory acquisition and retrieval. Theta coherence between mPFC and dorsal hippocampus, measured by both spike-theta phase locking and local field potential coherence, increases as the animal approaches a memory-guided choice point (Benchenane et al., 2010; Fujisawa and Buzsáki, 2011; Jones and Wilson, 2005). Further, this choice-related activity increases after acquisition of a new rule (Benchenane et al., 2010). Reductions in phase locking between mPFC spikes and hippocampal theta are also predictive of errors, suggesting that mPFC-hippocampal synchrony is either necessary for correct retrieval or, alternatively, reflects decision confidence (Hyman et al., 2010).

Discussion and Conclusion

As has been previously suggested, the mPFC likely forms and stores schema which map context and events onto appropriate actions (Alexander and Brown, 2011; Miller and Cohen, 2001). The purpose of these schema is to direct the correct emotional or motoric response to a given set of events in light of past experience

(Bechara and Damasio, 2005; Fellows, 2007). Here, we have explored how these schema are stored and retrieved on time scales ranging from seconds to weeks. Compared to primary motor cortex, the mPFC may have more capacity to maintain responses over brief periods of time (i.e., seconds). As such, it may provide a source of top-down control over motor cortex when action sets must be maintained (Narayanan and Laubach, 2006). For memories spanning more than a few seconds, the mPFC probably requires support from the hippocampus. With regard to consolidation of memory, the framework presented here suggests that the mPFC functions no different than any other area of the cortex. The hypothesized role of mPFC at different times after learning is depicted in Figure 5. During a phase of rapid consolidation occurring during the first few hours after learning, the hippocampus and mPFC replay the memories and, in so doing, synapses supporting that memory are strengthened in mPFC while they degrade in hippocampus. There is also likely a transformation from a memory for specific episodes to a more schematic representation (McCluskey et al., 1995; Winocur et al., 2010), though in most rodent studies, these two forms of memory are difficult to separate. In rats, this process of consolidation of the memory within mPFC continues for about two weeks (Takehara-Nishiuchi et al., 2006). A concomitant weakening of episodic traces in the hippocampus during this period might progressively shift the burden of remote recall to mPFC, hence explaining the enhanced dependence of remote memory on mPFC.

Why aren't all tasks involving motivated behavior impaired by mPFC lesions? Many simple tasks, such as instrumental conditioning or place-reward association are not dependent upon mPFC (Coutureau et al., 2012; Ragozzino et al., 1999). We suppose that the mPFC is one of many learning systems which operate in parallel. These other learning systems likely include the amygdala as well as other mPFC subregions and their associated striatal projection zones. In some cases, one system may be able to compensate for the loss of another. In other cases, learning in one system may forestall learning in another (Gruber and McDonald, 2012). Further complicating the search for mPFC function, loss of one area may shift learning to another area that would not otherwise be engaged. Hence, whether a task will depend on mPFC hinges on whether mPFC makes a unique contribution to that particular type of learning which cannot be handled by other areas. Exactly what that unique contribution is remains unclear; as suggested by Miller and Cohen (2001), contextual control of action is no doubt part of mPFC's role. However, the necessity of mPFC for contingency detection suggests that mPFC's role may be more specific, perhaps involving the extraction of temporal relationships between antecedents and outcomes (Coutureau et al., 2012). We contend that the functional lesion data are insufficient to fully constrain a theory of mPFC function at this time.

In our view, the strength of the framework presented here is that it provides a unified explanation for a broad range of memory studies. It also makes the specific prediction that in tasks involving contextual control of affect or action, the mPFC should be necessary for initial encoding, recent recall, and remote recall. The one caveat is that, during learning, other brain areas may be able to compensate for the lack of one or more mPFC

subregions. This supposition is itself testable. Imaging or inactivation studies should show that other areas, such as OFC, can compensate for the loss of mPFC during on-line learning. Once a task has been learned with mPFC intact, however, the mPFC will be needed for early consolidation as well as recent and remote retrieval. Our claim that mPFC is needed for recent memory is at odds with several studies showing a selective involvement of mPFC in remote but *not* recent memory (e.g., Frankland et al., 2004). However, as previously noted, our claim is supported by a few studies showing the necessity of mPFC for recent memory. We predict that closer examination of experiments demonstrating a selective mPFC role in remote memory will also show a weak involvement of mPFC in recent memory.

The framework presented here also makes specific predictions about the interactions between mPFC and the hippocampus. While the role of mPFC in working memory over a period of seconds remains a possibility, we suggest that any trial specific information maintained for minutes or hours is supported by the hippocampus. This is consistent with the finding that mPFC-hippocampal theta phase locking increases during the retrieval of short-term memory (e.g., Jones and Wilson, 2005). Further, both mPFC and hippocampus should be necessary for rapid consolidation after learning. Hence, we predict that every task which shows sensitivity to mPFC disruption during consolidation should similarly be sensitive to mPFC-hippocampal disconnection during the same interval.

SUPPLEMENTAL INFORMATION

Supplemental Information includes one table and can be found with this article online at <http://dx.doi.org/10.1016/j.neuron.2012.12.002>.

ACKNOWLEDGMENTS

The authors are supported by grants from Alberta Innovates Health Solutions (Polaris Award to B.L.M.), the Canadian Natural Sciences and Engineering Research Council to D.R.E and A.J.G., and the United States National Institute of Neurological Disorders and Stroke to B.L.M. and D.R.E.
